

Deep Bootstrap for Bayesian Inference

Lizhen Nie* and Veronika Ročková†

May 6, 2022

Abstract

For a Bayesian, the task to define the likelihood can be as perplexing as the task to define the prior. We focus on situations when the parameter of interest has been emancipated from the likelihood and is linked to data directly through a loss function. We survey existing work on both Bayesian parametric inference with Gibbs posteriors as well as Bayesian non-parametric inference. We then highlight recent bootstrap computational approaches to approximating loss-driven posteriors. In particular, we focus on implicit bootstrap distributions defined through an underlying push-forward mapping. We investigate iid samplers from approximate posteriors that pass random bootstrap weights through a trained generative network. After training the deep-learning mapping, the simulation cost of such iid samplers is negligible. We compare the performance of these deep bootstrap samplers with exact bootstrap as well as MCMC on several examples (including support vector machines or quantile regression). We also provide theoretical insights into bootstrap posteriors by drawing upon connections to model mis-specification.

Keywords: *Bootstrap, Likelihood-free Inference, Generative Networks.*

1 Introduction

While Bayesian’s obligation to specify a prior has been challenged the most, the obligation to specify the likelihood is perhaps even more consequential. Implicit in the Bayesian paradigm is the assumption that a probabilistic model can be formulated which links parameters with data. When constructing such a model, however, one has to reconcile bias implications of model mis-specification ([Grünwald and Van Ommen \(2017\)](#); [Müller \(2013\)](#)). Very often, the primary aim is not modeling the data but rather estimating a statistic.

Examples include M-estimators (Huber and Ronchetti (2009)) or other extremum estimators such as censored quantile regression (Powell (1986)), instrumental and robust median regression (Mood (1950)), nonlinear IV and GMM (Hansen and Singleton (1982)). For statistical inference, one may wish to obtain a post-data density summary of the parameter of interest rather than just a point estimate. Bayesian prior-to-posterior inference can be carried out even when one is reluctant about committing to a particular generative model.

One way how to liberate the inferential parameter θ_0 from the likelihood is by relating it to data through a general loss function. In medicine, for instance, minimal clinically important difference (Syring and Martin (2017)) or boundary detection in image analysis (Syring and Martin (2020b)) can be formulated as loss minimization problems. It is then possible to perform coherent Bayesian-style updating of prior beliefs, expressed in the prior $\pi(\theta)$, through the so-called Gibbs posteriors (Bissiri et al. (2016); Zhang (2006a,b)). This is a parametric generalization of classical Bayesian inference where the loss function is converted into a pseudo-likelihood function. Another way of expressing uncertainty about θ_0 is through a prior $\pi(F)$, as opposed to the prior $\pi(\theta)$, on the unknown data generating distribution function F_0 . Such non-parametric Bayesian inference (Chamberlain and Imbens (2003); Lyddon et al. (2019)) is based on the posterior of F rather than θ . We revisit both the non-parametric and parametric Bayesian approach (with Gibbs posteriors) to inference about parameter targets defined through loss functions.

Recalling the optimal information processing interpretation of the Bayes' rule (Knoblauch et al. (2019); Zellner (1988)), this paper surveys various generalizations of Bayesian inference (including variational inference (Jordan et al. (1999); Wainwright et al. (2008)) and Gibbs posteriors (Catoni (2004); Zhang (2006b))) under one unifying hat. In particular, we adopt the optimization-centric point of view on Bayes' rule which allows a re-interpretation of Bayesian inference as regularized optimization. Any commitment to a Bayesian posterior is a commitment to a particular optimization objective parametrized by the prior, the loss (log-likelihood) function and the class of post-data inferential densities (Knoblauch et al. (2019)). For example, variational Bayes forces the posterior belief into a specific parametric form, transforming the optimization from an infinite-dimensional into a finite-dimensional one. Gibbs posteriors, on the other hand, force priors and data into an exponentially additive relationship through loss functions. Alquier et al. (2016) combined the two by providing a VB computational alternative for Gibbs posteriors.

The repertoire of sampling methods for computing Gibbs posteriors depends on the availability of closed-form conditionals or computational resources. For example, classical MCMC sampling (using e.g. Metropolis-style samplers) may incur large computational costs (Johndrow et al. (2020); Quiroz et al. (2018)). As an alternative, this work investigates the recently proposed generative bootstrap sampler (Shin et al. (2020)) in the context of Bayesian simulation. This generative sampler is trained by learning a deterministic (deep learning) mapping between bootstrap weights and parameters to perform iid sampling. The iid aspect is particularly appealing because, after the mapping has been trained, the simulation cost is negligible compared to sequential samplers. We tailor the strategy of Shin et al. (2020) to the context of Bayesian simulation from approximate (1) Gibbs posteriors

for parametric Bayesian inference, and (2) non-parametric Bayesian posteriors. The goal is to learn an implicit distribution prescribed by a deterministic mapping that filters out bootstrap weights to produce samples from an approximate posterior. Implicit distributions have been loosely defined as distributions whose likelihoods are unavailable but which can be sampled from (Li and Turner (2018); Mohamed and Lakshminarayanan (2016)). While implicit distributions have been deployed for Bayesian computation before in the context of variational Bayes (Ruiz and Titsias (2019)), we explore implicit bootstrap distributions to generate samples from approximate posteriors.

Our main purpose is to (1) highlight several recent developments in loss-based Bayesian inference, and to (2) draw attention to generative samplers which are potentially very promising for Bayesian simulation. We investigate their benefits as well as limitations. We start off by describing loss-based Bayesian inference in Section 2. Section 3 is dedicated to an overview of bootstrap techniques for Bayesian computation. Section 4 provides some theoretical insights and Section 5 describes the performance of the generative bootstrap sampler for Bayesian inference in some classical examples.

1.1 Notation

We denote $[n]$ as the set $\{1, 2, \dots, n\}$, $\mathbf{1}_p \in \mathbb{R}^p$ as a vector of all 1's. We denote with $\|\cdot\|$ the Euclidean norm. For X , a random variable on a probability space (Ω, Σ, P) , and f , a function on Ω , we denote $\mathbb{P}(A) = \int_A dP$ for any $A \in \Sigma$, $\mathbb{E}[f(X)] = \int_{\Omega} f dP$, and also $Pf = \int_{\Omega} f dP$ to emphasize the underlying probability measure P .

2 Setting the Stage

Assume that we have observed a sequence of iid observations $X^{(n)} = (x_1, \dots, x_n)'$ from an unknown sampling distribution F_0 , i.e. $x_i \sim F_0$. Bayesian inference traditionally requires the knowledge of the true underlying model for F_0 . This essentially boils down to specifying a family of likelihood functions $\mathcal{F}_{\Theta} = \{p_{\theta}^{(n)}(X^{(n)}) : \theta \in \Theta\}$ indexed by an inferential parameter $\theta \in \Theta \subseteq \mathbb{R}^p$. When there is uncertainty about the parametric family \mathcal{F}_{Θ} and misspecification occurs, likelihood-based inference can be misleading (Kleijn and van der Vaart (2006)). Without the obligation to construct a probabilistic model, it may often be easier to infer about a target parameter θ that is directly tied to F_0 , such as the mean, median or other quantile. In other words, one can merely express an interest in some functional of F_0 as opposed to parameter attached to a particular model $p_{\theta}^{(n)}(X^{(n)}) = \prod_{i=1}^n p_{\theta}(x_i)$. Allowing \mathcal{F}_{Θ} to be unknown, Bissiri et al. (2016) formalized a Bayesian framework for rational updating of beliefs by connecting data to parameters of interest via loss functions. We revisit their development in the context of optimization-centric Bayesian inference.

2.1 Optimization-Centric Bayes

Bayesian learning from experience and evidence typically processes information from two sources: (1) a prior density $\pi(\theta)$ which extracts domain expertise, and (2) a likelihood function $p_\theta^{(n)}(X^{(n)})$ which distills the data. Famously, the Bayes' rule produces a post-data density summary for the parameters in a form of a posterior distribution $\pi(\theta | X^{(n)})$. There is, however, a conceptually different path for arriving at the posterior. Dating back to at least [Csiszár \(1975\)](#) and [Donsker and Varadhan \(1975\)](#), Bayes' theorem can be interpreted as the optimal information processing rule solving an infinite-dimensional optimization problem ([Zellner \(1988\)](#)). Through the optimization-centric lens ([Knoblauch et al. \(2019\)](#)), Bayesian inference is viewed as regularized optimization

$$\mathcal{L}(\ell; D; \Pi(\Theta)) \equiv \arg \min_{q \in \Pi(\Theta)} \left\{ \mathbb{E}_q \left[\sum_{i=1}^n \ell(\theta; x_i) \right] + D(q \| \pi) \right\} \quad (2.1)$$

indexed by a triplet of parameters: (1) a loss function ℓ , (2) a discrepancy function $D(\cdot \| \cdot)$ gauging the departure from the prior, and (3) a class of probability distributions $\Pi(\Theta)$ to optimize over. The classical likelihood-based Bayesian inference yields

$$\pi(\theta | X^{(n)}) = \mathcal{L}(-\log \pi_\theta(x); KL; \Pi(\Theta)) \quad (2.2)$$

where $\Pi(\Theta)$ is unconstrained and where KL stands for the Kullback-Leibler divergence. The solution of the optimization problem in (2.2) can be rewritten more transparently as (see proof of Theorem 1 in [Knoblauch et al. \(2019\)](#) or [Csiszár \(1975\)](#))

$$\pi(\theta | X^{(n)}) = \arg \min_{q \in \Pi(\Theta)} KL \left[q \parallel \pi(\theta) \exp \left\{ - \sum_{i=1}^n \ell(\theta; x_i) \right\} Z^{-1} \right], \quad (2.3)$$

where $Z = \int_\theta \exp\{-\sum_{i=1}^n \ell(\theta; x_i)\} \pi(\theta) d\theta$ is the norming constant (assumed to be finite). From (2.3) it can be seen that the optimization problem (2.1) forces priors and losses (log-likelihoods) into an exponentially additive relationship. If the KL term was absent from (2.2), the solution would be a Dirac measure concentrated at the MLE estimator. The incorporation of the prior $\pi(\theta)$ through the KL term in (2.1) allows one to obtain post-data densities for parameters in order to quantify uncertainty and to perform belief updating. The formula (2.3) is a template for generating belief distributions in more general situations, as will be seen below, through information theory.

The information-theoretic representation (2.1) reveals that committing to any particular Bayesian posterior is equivalent to committing to a particular optimization problem determined by (a) the loss function ℓ , (b) the discrepancy metric D , and (c) the space of probability measures $\Pi(\Theta)$. [Knoblauch et al. \(2019\)](#) presents various generalizations of Bayesian inference by altering the parameters $(\ell; D; \Pi(\Theta))$ of the optimization objective in (2.1). For example, constraining the class of distributions $\Pi(\Theta)$ to some parametric form is equivalent to the variational Bayes approach ([Wainwright et al. \(2008\)](#)). Alternatively, replacing the self-information loss $\ell(\theta; x) = -\log \pi_\theta(x)$ with any other loss function, one obtains the so called Gibbs posteriors (more below). Following [Knoblauch et al. \(2019\)](#), we regard (2.1) as the unifying hat behind various generalized Bayesian inference methods.

2.2 Bayesian Inference with Gibbs Posteriors

Sometimes, the parameter interest θ is defined indirectly through a general loss function $\ell(\theta; x)$ rather than the likelihood function. For an unknown distribution function F_0 , from which we observe an iid vector $X^{(n)}$, one can define such inferential target θ_0 as the minimizer of the average loss (Bissiri et al., 2016)

$$\theta_0 = \theta(F_0) \equiv \arg \min_{\theta \in \Theta} \int \ell(\theta; x) dF_0(x). \quad (2.4)$$

Replacing F_0 with the empirical distribution function P_n of $X^{(n)}$, one obtains an empirical risk minimizer, for example an M-estimator (Huber, 1981; Huber and Ronchetti, 2009; Maronna et al., 2006). In econometrics, extremum estimators (e.g. censored quantile regression of Powell (1986) or instrumental and robust median regression Mood (1950)) are also defined as maximizers of a random finite-sample criterion function whose population counterpart is maximized uniquely at some point $\theta_0 \in \Theta$. In these examples, θ_0 generally cannot be understood as a model parameter but rather as a solution to an optimization (loss minimization) problem. Chernozhukov and Hong (2003) note that implementing such estimators can be challenging and introduce quasi-Bayesian estimators for estimation and inference. Bissiri et al. (2016) propose a related general framework for updating belief distributions as a Bayesian extension of M-estimation. Indeed, even when the parameter cannot be directly assigned any particular model interpretation, it is still possible to perform Bayesian belief updating and uncertainty quantification.

In particular, Bissiri et al. (2016) suggest a decision-theoretic representation of beliefs about θ via a composite loss function over probability measures which gauges fidelity to data and departure from the prior (Berger (1993)). Curiously, their loss function corresponds to the optimization objective in (2.1) where the log-likelihood has been replaced by a general loss function $\ell(\theta; x)$ and where $D(\cdot \| \cdot)$ is the KL divergence. Similarly as in Section 2.1, it can be shown that the optimal distribution which minimizes this cumulative loss function (without constraining $\Pi(\Theta)$) has an exponentially additive form

$$\tilde{\pi}(\theta | X^{(n)}) = \frac{\pi(\theta) \exp \{-\alpha \sum_{i=1}^n \ell(\theta; x_i)\}}{\int_{\Theta} \pi(\theta) \exp \{-\alpha \sum_{i=1}^n \ell(\theta; x_i)\} d\theta}, \quad (2.5)$$

where $\alpha = 1$. Other values of $\alpha > 0$ have been considered to regulate the speed of the learning rate (see Grünwald (2012); Holmes and Walker (2017)). The distribution (2.5) is the “quasi-Bayesian” posterior introduced in Chernozhukov and Hong (2003) and it became known as the Gibbs posterior, a probability distribution for random estimators defined by an empirical measure of risk (Catoni (2004); Zhang (2006b)). The inferential object (2.5) now does not have the interpretation of the usual posterior but rather an optimal prior-to-posterior updating distribution that satisfies coherence and information preservation requirements.

The motivation for Gibbs posteriors can be traced back to the early work of Laplace (Laplace (1774)) who regarded a transformation of a least square criterion function as a statistical belief and obtained point estimates of that distribution “without any assumption

about the error distribution” (Stigler (1975)). In thermodynamics, the risk is interpreted as an energy function. In the PAC-Bayesian approach (McAllester (1998); Shawe-Taylor and Williamson (1997)), the Gibbs distribution appears as the probability distribution that minimizes the upper bound of an oracle inequality on the risk of estimators. Estimators derived from Gibbs posteriors, such as quasi-Bayesian mean or median (Chernozhukov and Hong, 2003), usually show excellent performance and yet their actual implementation can be challenging. The usual recommendation (Alquier and Biau (2013); Dalalyan and Tsybakov (2012)) is to sample from a Gibbs posterior using MCMC (see e.g. Green et al. (2015) or Ridgway et al. (2014) who propose tempering sequential Monte Carlo which may be too slow for practical use). Alquier et al. (2016) propose a variational Bayes approximation which can achieve the same rate of convergence as the actual Gibbs posterior and which has a polynomial time complexity in convex problems. Our work explores Bootstrap techniques and generative bootstrap samplers for approximating Gibbs posteriors, going beyond the development in Lyddon et al. (2019). Before delving into the implementation aspects, we distinguish the parametric inference approach with Gibbs posteriors (Bissiri et al. (2016); Chernozhukov and Hong (2003)) from the non-parametric Bayesian learning approach (Chamberlain and Imbens (2003); Lyddon et al. (2019)).

2.3 Bayesian Non-parametric Learning

Gibbs posteriors lock priors and losses in an exponentially additive relationship in order to achieve coherent Bayesian updating of beliefs. The uncertainty about the inferential target is a-priori represented in the prior distribution $\pi(\theta)$. The Bayesian non-parametric learning (NPL) approach (Chamberlain and Imbens (1996); Lyddon et al. (2019)), on the other hand, expresses uncertainty about θ through a prior on the unknown distribution function F_0 .

Defining the parameter of interest as a functional of F_0 (as in (2.4)), the focus is shifted from θ_0 to F_0 . Lyddon et al. (2019) propose a two-step Bayesian learning process by assigning a Dirichlet process (DP) prior $F \sim DP(\alpha, F_\pi)$ on the unknown distribution function F . The base measure F_π conveys prior knowledge about the sampling distribution F_0 and, indirectly, also the parameter θ_0 . In the first step, Bayesian non-parametric learning is used to form beliefs about the joint nonparametric density of data and then draws of the non-parametric density are made to repeatedly compute the extremum parameter of interest. Lyddon et al. (2019) call this sampling procedure the loss-likelihood bootstrap. Chamberlain and Imbens (1996) first introduced this strategy using a particular DP posterior (supported only on observations $X^{(n)}$ with Dirichlet-distributed probabilities for each state) that corresponds to the Bayesian bootstrap (Efron (1979)).

A suitable choice for the base measure F_π is the empirical distribution of the historical data. The second component of the DP prior the concentration parameter $\alpha > 0$ which can be re-interpreted as the effective sample size from the prior F_π . Assigning a DP prior on F_0 , the posterior $F | X^{(n)} \sim DP(\alpha + n, G_n)$ is also DP with the base measure updated as $G_n = \frac{\alpha}{\alpha+n} F_\pi + \frac{1}{\alpha+n} \sum_{j=1}^n \delta_{x_j}$. The posterior for the inferential target θ is then determined from this posterior through the mapping (2.4). In particular, under the stick-breaking

representation (Sethuraman (1994)) of the DP posterior, draws from $F | X^{(n)}$ are almost surely discrete and the parameter of interest, for each F , can be computed as

$$\theta(F) = \arg \min_{\theta} \sum_{k=1}^{\infty} w_k \times \ell(\theta; y_k)$$

where w_k 's are the stick-breaking beta-products and where y_k are iid samples from G_n . Drawing F from the DP posterior requires infinite time when F_{π} is continuous. Fong et al. (2019) suggest an approximate sampling scheme based on a truncation approximation of F_{π} and bootstrap-style sampling. The idea is to generate T fake data points \tilde{x}_j from F_{π} and assign each one a random weight \tilde{w}_j . The weights $\mathbf{w} = (w_1, \dots, w_n)'$ for the observed data and fake data $\tilde{\mathbf{w}} = (\tilde{w}_1, \dots, \tilde{w}_T)'$ are jointly sampled from a Dirichlet distribution $Dir(1, \dots, 1, \alpha/T, \dots, \alpha/T)'$. The posterior sample of the parameter $\theta(F)$ is then obtained by minimizing an augmented objective $\sum_{i=1}^n w_i \ell(x_i; \theta) + \sum_{j=1}^T \tilde{w}_j \ell(\tilde{x}_j; \theta)$. Bayesian bootstrap is obtained as a special case when $\alpha = 0$.

The non-parametric Bayesian learning approach (with Bayesian bootstrap (Efron (1979)) or the loss-likelihood bootstrap (Lyddon et al. (2019))) requires numerous re-computations of the extremum estimates in order to construct the posterior distribution over the parameter of interest. This can be prohibitively slow for optimization problems that are costly to solve. In this work, we investigate the possibility of deploying the generative Bootstrap sampler of Shin et al. (2020) that learns a deterministic mapping of weights $(\mathbf{w}, \tilde{\mathbf{w}})$ to obtain samples of $\theta(F)$.

3 Bootstrap for Bayesian Computation

Sampling methods are innate to Bayesian computation. Parallelizable iid sampling (with Approximate Bayesian Computation (Beaumont et al. (2002); Pritchard et al. (1999)) or bootstrap (Newton et al. (2021); Newton and Raftery (1994)) has certain privileges over sequential sampling with MCMC. ABC techniques are useful when the likelihood is easier to sample from than to evaluate. Bootstrap-style samplers (Efron (2012); Newton et al. (2021); Newton and Raftery (1994); Nie and Ročková (2022); Rubin (1981); Shin et al. (2020)), on the other hand, are beneficial when optimization is easier than, for example, sampling from conditionals. Below, we review recent developments in bootstrap-style posterior computation for Bayesian inference with loss functions.

Weighted likelihood bootstrap (WLB) of Newton and Raftery (1994) is a method for approximately sampling from a posterior distribution of a well-specified parametric statistical model. Samples are generated by computing randomly-weighted maximum likelihood estimates with the weights drawn from a suitable Dirichlet distribution. Such bootstrap samples are obtained as minimizers of randomly re-weighted objective functions, e.g.

$$\hat{\theta}_{\mathbf{w}} = \arg \min_{\theta} \left\{ \sum_{i=1}^n w_i \times \ell(\theta; x_i) - \lambda \log \pi(\theta) \right\} \quad (3.1)$$

for a given set of weights $\mathbf{w} \in \mathbb{R}^n$ drawn from some distribution H and for the log-likelihood loss function $\ell(\cdot; x_i)$. The WLB method is not an exact method and does not accommodate a prior (i.e. [Newton and Raftery \(1994\)](#) assume $\lambda = 0$). [Newton et al. \(2021\)](#) added a log-prior penalty to incorporate the prior with $\lambda > 0$. Conceivably, one can consider any general loss function $l(\cdot; y_i)$ and use alike strategy to sample from approximate Gibbs posteriors. We illustrate this in a Bayesian least absolute deviation regression example in [Section 5.2](#).

The WLB sampler can be in principle used to construct approximate quasi-posteriors ([Chernozhukov and Hong \(2003\)](#)), where the prior may need to be incorporated in some form either through distribution H or through a penalty term in [\(3.1\)](#). This aims at parametric-type inference with Gibbs posteriors (as described in [Section 2.2](#)). Loss-likelihood bootstrap ([Lyddon et al. \(2019\)](#)) reinterprets WLB as a sampler from an exact posterior over a parameter of interest defined through a loss function under an unknown sampling distribution. This aims at non-parametric Bayesian learning (as described in [Section 2.3](#)). This is also the strategy pursued in [Chamberlain and Imbens \(2003\)](#) based on the Bayesian bootstrap ([Rubin \(1981\)](#)).

3.1 Deep Bootstrap Sampling

Recall that the loss-likelihood bootstrap of [Lyddon et al. \(2019\)](#) generates samples

$$\hat{\theta}_{\mathbf{w}} = \theta(F_j) \quad \text{where} \quad F_j = \sum_{i=1}^n \delta_i w_i \quad (3.2)$$

with w_i 's arriving from, e.g., a Dirichlet distribution and where $\hat{\theta}_{\mathbf{w}}$ can be viewed as a minimizer of an expected loss under F_j as defined in [\(2.4\)](#). At a more intuitive level, each $\hat{\theta}_{\mathbf{w}}$ in [\(3.1\)](#) can be seen as a flexible functional of \mathbf{w} . This suggests a compelling possibility of treating the distribution of $\hat{\theta}_{\mathbf{w}}$ (be it an approximation to the Gibbs posterior or the non-parametric Bayesian posterior) as an implicit distribution. A distribution is implicit when it is not possible to evaluate its density but it is possible to draw samples from it. One typical way to draw from an implicit distribution is to first sample a noise vector and then push it through a deep neural network ([Mohamed and Lakshminarayanan \(2016\)](#)). Implicit distributions have been deployed within variational Bayes ([Pequignot et al. \(2020\)](#); [Ruiz and Titsias \(2019\)](#)) to obtain flexible distributional approximations to the posterior. Treating bootstrap distributions implicitly, the generative bootstrap sampler ([Shin et al. \(2020\)](#)) draws samples by learning a flexible mapping which transports weights \mathbf{w} onto parameters $\theta(F)$. A similar strategy can be used for the WLB approach of [Newton and Raftery \(1994\)](#) where $\hat{\theta}_{\mathbf{w}}$ is linked to \mathbf{w} through [\(3.1\)](#).

Instead of re-computing the optimization problem [\(3.1\)](#) for a freshly drawn set of weights \mathbf{w} at each step, [Shin et al. \(2020\)](#) suggest training a generator mapping, say $\hat{\theta}(\mathbf{w})$, which has to be learned only once. This mapping is designed to pass random weights w_j 's to yield samples from the bootstrap distribution, a sampling process which has negligible cost once the mapping has been learned. The following Lemma (Theorem 2.1 in [Shin et al. \(2020\)](#)) justifies this line of reasoning.

Figure 1: Prototype deep learning architecture from Shin et al. (2020).

Lemma 1. (Shin et al. (2020)) Assume that a function $G : \mathbb{R}^n \rightarrow \mathbb{R}^p$ is defined as

$$\hat{G}(\cdot) = \arg \min_{G \in \mathcal{G}} \mathbb{E}_{\mathbf{w}} \sum_{i=1}^n w_i \times \ell(G(\mathbf{w}); y_i) \quad (3.3)$$

where $\mathbb{E}_{\mathbf{w}}$ is the expectation with respect to $\mathbf{w} \sim H$. Moreover, assume that the solution $\hat{\theta}(\mathbf{w})$ defined in (3.1) is unique for each given $\mathbf{w} \in \mathbb{R}^n$. Then if \mathcal{G} is rich enough to express any function G we have

$$\hat{G}(\mathbf{w}) = \hat{\theta}_{\mathbf{w}}. \quad (3.4)$$

Proof. The proof is given in Section 2.2 of Shin et al. (2020) and rests on the simple observation that, since $\sum w_i l(\theta; y_i) \geq \sum w_i l(\hat{\theta}_{\mathbf{w}}; y_i)$, one has

$$\mathbb{E}_{\mathbf{w}} \sum_{i=1}^n w_i l(\hat{G}(\mathbf{w}); y_i) \geq \mathbb{E}_{\mathbf{w}} \sum_{i=1}^n w_i l(\hat{\theta}_{\mathbf{w}}; y_i)$$

which implies that $\hat{G}(\mathbf{w}) = \hat{\theta}_{\mathbf{w}}$.

The result in Lemma 1 implies an important “isomorphism” between bootstrap weights \mathbf{w} and parameters θ which can be exploited for faster computation of belief distributions (Gibbs posteriors in Section 2.2) or non-parametric Bayesian learning posteriors (Section 2.3). For training $G(\cdot)$, one may want to search within mappings \mathcal{G} that are compositions of non-linear transformations, i.e. a deep learning mappings. Due to the expressibility of neural networks (see e.g. Barron (1993)), the neural network estimator $\hat{G}(\cdot)$ can be made arbitrarily close to the optimal mapping that satisfies (3.4). This work uses forward deep learning mappings \mathcal{G} , thereby the name Deep Bootstrap Sampler.

The nested structure of neural networks allows for gradients to be efficiently evaluated using back-propagation (Hecht-Nielsen (1992); Rumelhart et al. (1986)). Once the gradient is computed, stochastic gradient descent algorithm can be used to update the parameters iteratively. Shin et al. (2020) also suggest a specific neural network architecture which re-introduces the weights at each layer. Such a deep approximating class with L network

Table 1 : Deep Bootstrap Sampler for Gibbs Posterior Learning

Data: Data $\{x_i, 1 \leq i \leq n\}$, number of training epochs T , number of points to sample N , number of Monte Carlo samples K , prior π , learning rate η , number of subgroups S for observed data, $n_S = n/S$ the size of each subgroup.

Result: $\theta^i, i = 1, 2, \dots, N$.

Training stage:

Initialize weights ϕ of the fitted function \hat{G} .

```

for  $t = 1, 2, \dots, T$  do
  for  $k = 1, 2, \dots, K$  do
    Draw  $\tilde{w}_{1:S}^k \sim S \times Dir(1, \dots, 1)$ .
    Set  $w_{(j-1)n_S+m}^k = \tilde{w}_j^k$  for all  $m = 1, 2, \dots, n_S, j = 1, 2, \dots, S$ .
  end
  Update  $\phi \leftarrow \phi - \eta \partial_\phi \left[ \sum_{k=1}^K \left[ \sum_{j=1}^n w_j^k l \left( G(\tilde{w}_{1:S}^k); x_j \right) + \log \pi \left( G(\tilde{w}_{1:S}^k) \right) \right] \right]$ .
end

```

Sampling stage:

```

for  $i = 1, 2, \dots, N$  do
  (2.1) Draw  $\tilde{w}_{1:S}^k \sim S \times Dir(1, \dots, 1)$ .
  (2.2) Evaluate  $\theta^i = \hat{G}_\phi(\tilde{w}_{1:S}^k)$ .
end

```

layers, each with n_l neurons, can be written as

$$\begin{aligned}
 g(\mathbf{w}) &= g_L(\mathbf{Z}_L) \\
 \mathbf{Z}_{l+1} &= \{g_l(\mathbf{Z}_l), \mathbf{w}\} \quad \text{for } 1 \leq l \leq L-1.
 \end{aligned}$$

where $\mathbf{Z}_1 = \mathbf{w}$ and where each function $g_l : \mathbb{R}^{n_l} \rightarrow \mathbb{R}^{n_{l+1}}$ squashes a multivariate linear combination of the input variables Z_l by a squashing function T , e.g. the Rectified Linear Unit (ReLU) or a sigmoid function. The parameters of the linear combinations for each layer (i.e. intercept terms and slopes) are encapsulated in a vector parameter ϕ .

In the neural network architecture proposed by Shin et al. (2020), the number of trainable parameters in the l -th layer is $O((n_l + n)n_l)$. When $n \gg n_l$, this number grows linearly in n and thus, reducing the dimension n of input will significantly improve the computational efficiency. Shin et al. (2020) proposed a subgroup bootstrap strategy, which groups the n weights into S equi-sized blocks and $S \ll n$. The weights in the same group are assigned the same value. The S weights are drawn from some distribution H_α . Then the number of trainable parameters in the l -th layer will be reduced to $O((n_l + S)n_l)$. The subgroup strategy significantly boosts the computational advantage of Deep Bootstrap samplers. The architecture incorporating this strategy is shown in Figure 1. We summarize the Deep Bootstrap sampler for Bayesian parametric learning with Gibbs posteriors in Algorithm 1 and for Bayesian non-parametric learning in Algorithm 2.

Table 2 : Deep Bootstrap Sampler for Bayesian NPL

Data: Data $\{x_i, 1 \leq i \leq n\}$, number of prior pseudo samples n' , number of training epochs T , number of points to sample N , number of Monte Carlo samples K , concentration parameter α , learning rate η , number of subgroups S for observed data, number of subgroups S' for prior pseudo data, $n_S = n/S, n_{S'} = n/S'$.

Result: $\theta^i, i = 1, 2, \dots, N$.

Training stage:

Initialize weights ϕ of the fitted function \hat{G} .

Approximate the prior by drawing $x'_{1:n'} \stackrel{\text{iid}}{\sim} F_\pi$.

Create the enlarged (observed + prior pseudo) sample $\{x_1, \dots, x_n, x'_1, \dots, x'_{n'}\}$.

for $t = 1, 2, \dots, T$ **do**

for $k = 1, 2, \dots, K$ **do**

Draw $\tilde{w}_{1:(S+S')}^k \sim (S + S') \times \text{Dir}(1, \dots, 1, \alpha/n', \dots, \alpha/n')$.

Set $w_{(j-1)n_S+m}^k = \tilde{w}_j^k$ for any $m \in [n_S], j \in [S]$ and $w_{n+(j'-1)n_{S'}+m'}^k = \tilde{w}_{j'+S}^k$, for any $m' \in [n_{S'}], j' \in [S']$.

end

Update $\phi \leftarrow \phi - \eta \partial_\phi \left[\sum_{k=1}^K \left[\sum_{j=1}^n w_j^k l(G(\tilde{w}_{1:(S+S')}^k); x_j) + \sum_{j=1}^{n'} w_{j+n}^k l(G(\tilde{w}_{1:(S+S')}^k); x'_j) \right] \right]$.

end

Sampling stage:

for $i = 1, 2, \dots, N$ **do**

(2.1) Draw $\tilde{w}_{1:(S+S')}^k \sim (S + S') \times \text{Dir}(1, \dots, 1, \alpha/n', \dots, \alpha/n')$.

(2.2) Evaluate $\theta^i = \hat{G}_\phi(\tilde{w}_{1:(S+S')}^k)$.

end

4 Theory

The quantification of the speed of concentration around the truth (as the sample size goes to infinity) is now a standard way of assessing the quality of posteriors (Ghosal et al. (2000)). As Shalizi (2009) states, such Bayesian asymptotic results are “frequentist license for Bayesian practice”. Below, we review recent literature related to our development and provide theoretical support for certain aspects of the weighted likelihood bootstrap using connections to model misspecification.

Bhattacharya et al. (2019) studied concentration of the so-called fractional α -posteriors obtained by raising the likelihood to some fixed value $\alpha \in (0, 1)$. We study bootstrap-style posteriors where each observation is raised to a *different random* weight w_i where $\sum_{i=1}^n w_i = n$. Bhattacharya et al. (2019) proved that the fractional α -posteriors concentrate on the so-called α -divergence neighborhoods around the truth. The α -divergence is shown to be a valid divergence measure when $\alpha \in (0, 1)$, and the rate of contraction is inflated by a multiplicative factor $\frac{1}{1-\alpha}$. This line of proof, unfortunately, does not extend easily to our bootstrap-style posteriors.¹ We study the distribution of extremal (modal) estimators

¹Unless $w_i = 1$ for all i 's, there must be some weight $w_i > 1$. The existence of such weights invalidates the upper bound in Bhattacharya et al. (2019), and we find it difficult to define a similar (and valid) divergence measure that could be properly upper bounded.

$\hat{\theta}_{\mathbf{w}}$ defined in (3.1) when $\lambda = 1$. While the α -posteriors keep the weight fixed and the randomness stems from treating θ as a random variable with a prior, we treat $\hat{\theta}_{\mathbf{w}}$ as an estimator where the randomness comes from \mathbf{w} . In a related paper, Han and Yang (2019) study contraction of weighted posterior distributions incorporating both the randomness of θ (through the weighted posterior distribution under the prior $\pi(\theta)$) and the randomness of \mathbf{w} (from the distribution of weights $\pi(\mathbf{w})$). Our theory has two parts. First, in our Theorem 4.2, we obtain a similar conclusion to Han and Yang (2019) but using a different proving technique. There we focus on the entire weighted posteriors assuming that $\ell(x; \theta)$ in (3.1) is the unit information loss. We refer to Syring and Martin (2020a) for concentration-rate results for the actual Gibbs posteriors with sub-exponential loss functions. Second, we are interested in the contraction of a distribution of weighted posterior modes $\hat{\theta}_{\mathbf{w}}$ around θ_0 . This property is summarized in Theorem 4.3, where we consider losses other than just the unit information loss.

First, we want to understand the behavior of the weighted posteriors

$$\pi_{\mathbf{w}}(\theta | X^{(n)}) = \frac{\pi(\theta)p_{\theta}^{(n),\mathbf{w}}(X^{(n)})}{\int_{\Theta} \pi(\theta)p_{\theta}^{(n),\mathbf{w}}(X^{(n)})d\theta} \propto e^{u_{\theta,\mathbf{w}}(X^{(n)})}p_{\theta}^{(n)}(X^{(n)})\pi(\theta),$$

where the exponential tilting factor

$$u_{\theta,\mathbf{w}}(X^{(n)}) = \log \frac{p_{\theta}^{(n),\mathbf{w}}(X^{(n)})p_{\theta_0}^{(n),1-\mathbf{w}}(X^{(n)})}{p_{\theta}^{(n)}(X^{(n)})}$$

combines individually weighted likelihood terms (with weights w_i and $1 - w_i$)

$$p_{\theta}^{(n),\mathbf{w}}(X^{(n)}) = \prod_{i=1}^n p_{\theta}^{w_i}(X_i) \quad \text{and} \quad p_{\theta_0}^{(n),1-\mathbf{w}}(X^{(n)}) = \prod_{i=1}^n p_{\theta_0}^{1-w_i}(X_i).$$

Following Kaji and Rockova (2021), for any fixed \mathbf{w} , $\pi_{\mathbf{w}}(\theta | X^{(n)})$ can be viewed as the posterior density under a mis-specified likelihood

$$\tilde{p}_{\theta}^{(n),\mathbf{w}}(X^{(n)}) = \frac{e^{u_{\theta,\mathbf{w}}(X^{(n)})}p_{\theta}^{(n)}(X^{(n)})}{C_{\theta,\mathbf{w}}} \quad \text{where} \quad C_{\theta,\mathbf{w}} = \int_{\mathcal{X}} e^{u_{\theta,\mathbf{w}}(X^{(n)})}p_{\theta}^{(n)}(X^{(n)})dX^{(n)},$$

and a modified prior

$$\tilde{\pi}_{\mathbf{w}}(\theta) = \frac{C_{\theta,\mathbf{w}} \times \pi(\theta)}{\int_{\Theta} C_{\theta,\mathbf{w}} \times \pi(\theta)}. \quad (4.1)$$

Note that $P_{\theta_0}^{(n)}$ is *not* of the same form as $\tilde{\mathcal{P}}^{(n),\mathbf{w}} = \{\tilde{P}_{\theta}^{(n),\mathbf{w}} : \theta \in \Theta\}$. This new mis-specification perspective allows us to use a different proving technique from Bhattacharya et al. (2019) and Han and Yang (2019). It is known (Kleijn and van der Vaart (2006)) that under the mis-specified model $\tilde{p}_{\theta}^{(n),\mathbf{w}}$, the posterior will concentrate around the KL-projection point $\theta_{\mathbf{w}}^*$ defined as

$$\theta_{\mathbf{w}}^* = \arg \min_{\theta \in \Theta} -P_{\theta_0}^{(n)} \log \frac{\tilde{p}_{\theta}^{(n),\mathbf{w}}(X^{(n)})}{p_{\theta_0}^{(n)}(X^{(n)})}. \quad (4.2)$$

At first sight, since the model $\tilde{p}_\theta^{(n),\mathbf{w}}$ is mis-specified and depending on the value of \mathbf{w} , $\theta_{\mathbf{w}}^*$ will not necessarily be the true target θ_0 . Surprisingly, under some mild conditions on \mathbf{w} , θ_0 will be the unique minimizer of Equation (4.2), i.e., $\theta_0 = \theta_{\mathbf{w}}^*$. This is stated in the next Lemma.

Lemma 4.1. *Assume that: (1) there exists $i \in [n]$ such that $w_i > 0$, and (2) the random variable $Z(X_i) = \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)}$ is degenerate only if $\theta = \theta_0$. Then*

$$\theta_0 = \arg \min_{\theta \in \Theta} -P_{\theta_0}^{(n)} \log \frac{\tilde{p}_\theta^{(n),\mathbf{w}}(X^{(n)})}{p_{\theta_0}^{(n)}(X^{(n)})}, \quad \text{i.e.,} \quad \theta_{\mathbf{w}}^* = \theta_0.$$

Proof. See Appendix Section A.2.

The lemma says that even though we perturb the likelihood, the truth θ_0 still optimizes the KL divergence between the mis-specified likelihood $\tilde{p}_\theta^{(n),\mathbf{w}}$ and the true likelihood $p_{\theta_0}^{(n)}$. The intuitive explanation is that

$$\tilde{p}_\theta^{(n),\mathbf{w}} = C_{\theta,\mathbf{w}}^{-1} p_{\theta_0}^{(n),1-\mathbf{w}} p_\theta^{(n),\mathbf{w}}.$$

The mis-specified likelihood $\tilde{p}_\theta^{(n),\mathbf{w}}$ can be thereby viewed as the original likelihood $p_{\theta_0}^{(n)}$ adjusted towards $p_\theta^{(n)}$, where the strength of adjustment depends on \mathbf{w} . When $\theta = \theta_0$, we always have $\tilde{p}_\theta^{(n),\mathbf{w}} = p_{\theta_0}^{(n)}$, regardless of the weights \mathbf{w} . To start, using Lemma 4.1, we can conclude concentration-rate result for the whole posterior $\pi_{\mathbf{w}}(\theta | X^{(n)})$ around the truth θ_0 . Define $R_n(c_0) = \{(a_1, a_2, \dots, a_n)' \in \mathbb{R}^n : a_i \geq 0, \sum_{i=1}^n a_i = n, \max_{i \in [n]} a_i \leq c_0 \log n\}$.

Theorem 4.2. *Assume that there exists a constant $c_0 > 0$ and a sequence of real numbers $\epsilon_n > 0$ with $\epsilon_n \rightarrow 0, n\epsilon_n^2 \rightarrow \infty$, such that the sequence of sets $R_n(c_0)$ satisfies*

$$\mathbb{P}_{\mathbf{w}}[\mathbf{w}_n \in R_n(c_0)] \rightarrow 1. \tag{4.3}$$

Under technical Assumptions 1, 2, 3 in the Appendix (Section A.3) and the assumptions in Lemma 4.1 we have

$$P_{\theta_0}^{(n)} P_{\mathbf{w}} \left[\Pi_{\mathbf{w}} \left(\|\theta - \theta_0\| > M_n \epsilon_n \mid X^{(n)} \right) \right] \rightarrow 0$$

for any sequence $M_n \rightarrow \infty$ as $n \rightarrow \infty$, where $\Pi_{\mathbf{w}}(\cdot | X^{(n)})$ is the probability measure associated with the posterior density $\pi_{\mathbf{w}}(\cdot | X^{(n)})$.

Proof. See Appendix Section A.3.

Han and Yang (2019) obtained a similar result under stronger differentiability assumptions on both the prior and the likelihood to achieve a parametric rate (up to a logarithmic factor). Our Theorem 4.2 assumes a prior mass and testing conditions, yielding a more general concentration rate (not necessarily $1/\sqrt{n}$). In addition, our proving technique is different and uses the model mis-specification perspective.

We are ultimately interested in the convergence of posterior modes $\hat{\theta}_{\mathbf{w}}$ around θ_0 where the randomness is driven by \mathbf{w} . Theorem 4.2 implies the existence of a point estimator based

on $\Pi_{\mathbf{w}}(\cdot | X^{(n)})$ that converges to the truth at a rate ϵ_n for each \mathbf{w} (e.g., using Theorem 8.7 in Ghosal and Van der Vaart (2017)). In Theorem 8.8 of Ghosal and Van der Vaart (2017), for example, it is shown that for convex distances, the posterior mean converges at a rate ϵ_n . The convergence rate might be adopted also by the posterior mode under suitable local asymptotic normality conditions. We have chosen a different, more direct, route to show the convergence of posterior modes $\hat{\theta}_{\mathbf{w}}$.

We utilize tools for establishing convergence rates for M-estimators (Van der Vaart and Wellner (1996)). We denote with $p_{\theta}(x) = \exp\{-l(\theta; x)\}$ an exponentiated loss, not necessarily a likelihood, and we show that $\hat{\theta}_{\mathbf{w}}$ concentrates around the inferential target θ_0 defined in Equation (2.4).

We denote $\mathcal{M}_{\epsilon}(\theta_0) = \{\log[p_{\theta}/p_{\theta_0}] : d(\theta, \theta_0) < \epsilon\}$, and P_0 the probability measure of X_i 's, i.e., $X_i \stackrel{\text{iid}}{\sim} P_0$. For any function class \mathcal{F} , we write its Rademacher complexity with respect to P_0 for the sample size n as $\mathcal{R}_n(\mathcal{F})$, i.e.,

$$\mathcal{R}_n(\mathcal{F}) = P_0^{(n)} \left[\sup_{f \in \mathcal{F}} \left| \frac{1}{n} \sum_{i=1}^n \sigma_i f(X_i) \right| \right],$$

where $\mathbb{P}(\sigma_i = 1) = \mathbb{P}(\sigma_i = -1) = 1/2$ for any $i \in [n]$. Denote $\phi_n(\epsilon) = \sqrt{n} \mathcal{R}_n(\mathcal{M}_{\epsilon}(\theta_0))$. The following theorem establishes the convergence rate of the posterior modes $\hat{\theta}_{\mathbf{w}}$. We allow the prior π to depend on the sample size n , and we thereby write π_n for emphasis.

Theorem 4.3. *Assume that:*

(1) *(Existence of a suitable semi-metric) There exists a semi-metric $d(\cdot, \cdot)$ on Θ such that*

$$P_0 \log[p_{\theta_0}/p_{\theta}] \geq d^2(\theta, \theta_0) \quad \text{for all } \theta \in \Theta,$$

(2) *(Bounded loss) $\sup_{\theta \in \Theta} |\log p_{\theta}(X)| < \infty$,*

(3) *(Weight regularization) The weights satisfy*

$$w_i \text{ i.i.d. with } \mathbb{E}w_i = 1, \|w_i\|_{2,1} = \int_0^{\infty} \sqrt{P(|w_i| > x)} dx < \infty, \quad \text{or} \quad (4.4)$$

$$\mathbf{w}_n = (w_1, \dots, w_n) \sim n \times \text{Dir}(c, \dots, c), \quad \text{for some fixed } c > 0. \quad (4.5)$$

(4) *(Proper growth of Rademacher complexity) There exist constants $C > 0$, $\gamma \in (0, 2)$ such that for all $\epsilon > 0$, $c > 1$,*

$$\phi_n(\epsilon) \leq C \sqrt{n} \epsilon^2, \quad \phi_n(c\epsilon) \leq c^{\gamma} \phi_n(\epsilon).$$

Then, for any $M_n \rightarrow \infty$ as $n \rightarrow \infty$, we have

$$P_0^{(n)} \mathbb{P}_{\mathbf{w}} \left(d(\hat{\theta}_{\mathbf{w}}, \theta_0) > M_n \epsilon_n \right) \rightarrow 0,$$

where $\epsilon_n \rightarrow 0$ satisfies

$$\epsilon_n^{-2} \phi_n(\epsilon_n) \leq \sqrt{n} \text{ for all } n \quad \text{and} \quad \sup_{\epsilon \geq \epsilon_n} \frac{\sup_{\theta \in \Theta: \epsilon < d(\theta, \theta_0) \leq 2\epsilon} \log \frac{\pi_n(\theta)}{\pi_n(\theta_0)}}{n \epsilon^2} \rightarrow 0. \quad (4.6)$$

Proof. See Appendix A.4.

Remark 1 (Discussion on the convergence rate). *Theorem 4.3* establishes a general (not necessarily \sqrt{n}) rate of convergence for the distribution of posterior modes. The first part of Equation (4.6) is similar to previous conclusions for M -estimators (Van der Vaart and Wellner (1996)). It shows that the convergence rate for $\hat{\theta}_{\mathbf{w}}$ is driven by the growth of $\mathcal{R}_n(\mathcal{M}_\epsilon(\theta_0))$ around $\epsilon = 0$, which is determined by the richness of the function class $\{\log p_\theta : \theta \in \Theta\}$ around $\theta = \theta_0$. For example, with monotone densities, $\epsilon_n = n^{-1/2}$ and with convex densities in \mathbb{R}^d , $\epsilon_n = n^{2/(d+4)}$ for $d \leq 3$, $\epsilon_n = n^{1/4}/[\log(n)]^{1/2}$ for $d = 4$ and $\epsilon_n = n^{1/d}$ for $d > 4$. We refer interested readers to Pollard (1991); Van der Vaart and Wellner (1996) for more examples. The second part of (4.6) is less common, and it says that the convergence rate will also be affected by prior $\pi_n(\theta)$. In particular, a sufficient prior mass has to be put around $\theta = \theta_0$, otherwise the convergence rate will be slowed.

Remark 2 (Errors from deep learning approximation). We note that all previous results refer to the actual posterior, not the Deep Bootstrap approximation. In other words, we do not consider the estimation error in obtaining $\hat{\theta}_{\mathbf{w}}$ using the deep learning approximations. Theoretically, there always exists a sufficiently large neural network whose approximation error is sufficiently small (Gühring et al. (2020); Hornik et al. (1989)). Thus, if we allow its size to grow at a proper rate, we might show existence of a sequence of networks whose mapping converges at a rate no slower than ϵ_n . The actual estimation error of the trained neural network, however, would need to incorporate the actual optimization of the network.

5 Deep Bootstrap in Bayesian Practice

This section presents several stereotypical toy examples of inference about parameters determined by loss-functions. We aim to illustrate the potential of the deep bootstrap sampler for Bayesian inference.

5.1 Bayesian Support Vector Machines

We first demonstrate the performance of the Deep Bootstrap sampler for Bayesian non-parametric learning (Section 2.3) in binary classification tasks. Given data $\{(y_i, \mathbf{x}_i) \in \{-1, 1\} \otimes \mathbb{R}^p\}_{i=1}^n$ where \mathbf{x}_i denotes the covariates of the i^{th} observation with a binary label $y_i \in \{-1, +1\}$, binary classification aims to predict y when given \mathbf{x} using the sign of $f(x)$, where $f : \mathbb{R}^p \rightarrow \mathbb{R}$ is a function to be learned. Various loss functions have been designed to learn f , including the Support Vector Machine (SVM) loss (Cortes and Vapnik (1995))

$$L(y, f(\mathbf{x})) = \max\{0, 1 - yf(\mathbf{x})\},$$

and the logistic loss (Pearl and Reed (1920))

$$L(y, f(\mathbf{x})) = \log(1 + e^{-yf(\mathbf{x})}).$$

Suggested by [Rosasco et al. \(2004\)](#), we choose the SVM loss with a linear f , i.e., we minimize the empirical loss $\sum_{i=1}^n l(\beta, \boldsymbol{\theta}; y_i, \mathbf{x}_i)$ with

$$l(\beta, \boldsymbol{\theta}; y_i, \mathbf{x}_i) = \max\{0, 1 - y_i(\beta + \mathbf{x}_i' \boldsymbol{\theta})\}, \quad (5.1)$$

where $\beta \in \mathbb{R}$ is the bias and $\boldsymbol{\theta} = (\theta_1, \dots, \theta_p)' \in \mathbb{R}^p$ are the regression coefficients. For the DP prior, following [Fong et al. \(2019\)](#), we use the prior centering measure

$$\begin{aligned} F_\pi(y, \mathbf{x}) &= F_\pi(\mathbf{x})F_\pi(y), \quad \text{where} \\ F_\pi(\mathbf{x}) &= \frac{1}{n} \sum_{i=1}^n \delta_{\mathbf{x}_i}, \quad \text{with } \delta_{\mathbf{x}} \text{ the Dirac delta measure centered at } \mathbf{x}, \\ F_\pi(y) &= \text{Bernoulli}(0.5). \end{aligned} \quad (5.2)$$

As discussed in [Fong et al. \(2019\)](#), this choice of F_π assumes that y, \mathbf{x} are independent and thus is equivalent to assuming $\boldsymbol{\theta} = \mathbf{0}_p$ a priori, which induces similar effects as shrinking priors on $\boldsymbol{\theta}$ (for example, $\|\boldsymbol{\theta}\|_1$ or $\|\boldsymbol{\theta}\|_2$). Regarding the choice of the concentration parameter α , larger α represents stronger beliefs in the prior. Here, following [Fong et al. \(2019\)](#), we set $\alpha = 1.0$.

To generate simulated data sets, we adopt the setting in [Lyddon et al. \(2019\)](#) and extend to multivariate \mathbf{x} 's: we sample n i.i.d. data points $\{(y_i, \mathbf{x}_i)\}_{i=1}^n$ from

$$\mathbb{P}(y_i = 1) = \mathbb{P}(y_i = -1) = 1/2, \quad \mathbf{x}_i \mid y_i \sim N(y_i \mathbf{1}_p, \Sigma), \quad (5.3)$$

where Σ is a $p \times p$ matrix with all 1's on the diagonal and ρ 's off-diagonally. We consider $\rho = 0$ (independent covariates) and a more challenging case $\rho = 0.6$ (equi-correlated covariates). For brevity, results for the independent case is deferred to the Appendix (Section [B.3](#)). Note that with Equation [\(5.3\)](#), the inferential target $\theta_0 = (\beta, \boldsymbol{\theta})$ is a solution to the optimization problem defined in Equation [\(2.4\)](#), which does not have a closed form solution for the loss [\(5.1\)](#) and which does not necessarily satisfy $\beta = 0, \boldsymbol{\theta} = \mathbf{1}_p$. For example, when $p = 10, \rho = 0.6$, we have $\beta \approx 0, \boldsymbol{\theta} \approx 0.2 \times \mathbf{1}_p$ by solving [\(2.4\)](#) numerically. The misalignment between the inferential target $\theta_0 = (\beta, \boldsymbol{\theta})$ and the truth $(0, \mathbf{1}_p)$ is not harmful for binary classification tasks as prediction is usually of more interest. We consider varying samples sizes $n \in \{50, 500, 1000, 2000, 5000\}$ and dimensions of covariates $p \in \{10, 50, 100, 200, 500\}$.

We use the deep learning architecture (Figure [1](#)) introduced in [Shin et al. \(2020\)](#) to fit the Deep Bootstrap sampler. As discussed in [Shin et al. \(2020\)](#), the benefit of this structure is that the re-introduction of weights at each hidden layer helps “gradient flow in training deep neural networks” and thus alleviates any potential variance underestimation issues. Using the notation in Section [3.1](#), we set $L - 1 = 3$ fully connected (linear function + ReLU) hidden layers, each containing 128 neurons. Our sensitivity analysis in Appendix [B.1](#) shows that the network architecture has an impact on the approximating performance of the Deep Bootstrap sampler, yet such impact is minimal once the network complexity is moderately large (for example, $L - 1 = 3, n_l = 128, l = 1, 2, 3$ suffices for all experiments we tried). The implementation follows Algorithm [2](#) and is coded via an optimized machine learning framework PyTorch ([Paszke et al. \(2017\)](#)). As suggested by [Shin et al. \(2020\)](#),

Figure 2: Two-dimensional posterior density plot for θ_i 's from deep Bootstrap sampler and the truth for the Bayesian support vector machine example. We set $n = 50, p = 10, \rho = 0.6, \alpha = 1.0$.

we use subgroup bootstrap with $S = 100$ and $S' = 10$. The subgroup bootstrap strategy significantly boosts the computational benefit of deep Bootstrap samplers (DBS), and does not hurt much its performance in our experiments. We set the number of Monte Carlo samples $K = 100$, learning rate η initialized at 0.0003 and following a decay rate of $t^{-0.3}$ where t is the current number of epoch (Shin et al. (2020)). In all (n, p) 's we tried, the training usually stabilizes after around 2000 iterations, and we set $T = 4000$ to ensure convergence. RMSprop algorithm (Graves (2013)) is used to update the gradients instead of the vanilla gradient descent in Algorithm 2.

Sampled points $\{\theta^1, \dots, \theta^N\}$ from the true bootstrap distribution are generated following Algorithm 2 in Fong et al. (2019). It requires solving an optimization problem

$$\theta^j = \arg \max_{(\beta, \boldsymbol{\theta})} \sum_{i=1}^n w_i \times l(\beta, \boldsymbol{\theta}; y_i, \mathbf{x}_i) + \sum_{i=1}^{n'} w_{i+n} \times l(\beta, \boldsymbol{\theta}; y'_i, \mathbf{x}'_i), \quad \forall j = 1, 2, \dots, N, \quad (5.4)$$

with $l(\beta, \boldsymbol{\theta}; y_i, \mathbf{x}_i)$ defined in (5.1), $(\mathbf{x}'_i, y'_i) \stackrel{\text{iid}}{\sim} F_\pi(y, \mathbf{x})$ where F_π is defined in (5.2), and the set of weights $(w_1, \dots, w_{n+n'})$ are drawn from $Dir(1, \dots, 1, \alpha/n', \dots, \alpha/n')$. Here n' is the number of pseudo-samples and we set $n' = n$. We solve the optimization problem (5.4) using the function `linear_model.SGDClassifier` in Python library `sklearn` (Pedregosa et al. (2011)). This function allows various loss functions and different weight w_i 's for each sample point, and optimizes the loss function via stochastic gradient descent. We use the adaptive learning rate schedule (Pedregosa et al. (2011)) and tune the initial learning rate among $\{0.0001, 0.001, 0.01, 0.1\}$. The maximum number of epochs is set to 20000 with early stopping turned on for saving computations.

To evaluate the performance of the Deep Bootstrap sampler, we first consider the two-dimensional density plots of θ_j 's. Figure 2 depicts an example where $n = 50, p = 10, \rho = 0.6$. We observe that the Deep Bootstrap sampler captures the bootstrap posterior mean, but less so its variance. This issue has been discussed in Shin et al. (2020). Shin et al. (2020) believe that it is caused by the vanilla feed-forward neural network which prevents variation in the input weights to properly transmit to the output layers as the neural network grows deeper, and they propose the network structure in Figure 1 to alleviate it. Here, we observe that this issue still persists when applied to Bayesian models. The study in Appendix B.2 shows that for Bayesian models, as the sparsity-inducing prior grows stronger, the Deep Bootstrap sampler goes from accurate or slight over-estimation of the variance to more and

Table 1: Evaluation of approximation properties based on 10 independent runs for Bayesian support vector machine example. DBS stands for ‘deep Bootstrap sampler’. WLB stands for samples from the true bootstrap distribution. ‘Bias’ refers to the l_1 distance of estimated posterior means. ‘ROC’ refers to the area under the receiver operating characteristic curve; ‘PR’ refers to the area under the precision-recall curve. The last column in each setting represents the time (in seconds) to generate 10 000 sample points. For deep Bootstrap sampler, time reported is in the form of training time + sampling time.

more severe underestimation. We emphasize that, usually, the variance mismatch issue is not severe as long as the regularization strength is properly selected (e.g., using the BIC criterion (Schwarz (1978))) as in the next example). In this example (with $\alpha = 1.0$), it does not affect the predictive inference on testing data, which is shown in Table 1.

In Table 1, we measure the ability of the Deep Bootstrap sampler to approximate the bootstrap target in terms of predictive performance. For each x_i , we assign an ‘average’ label by the majority vote based on samples of (β, θ) . We report quantitative metrics that reflect the quality of this average (accuracy, precision, recall, F1 score). In addition, we report metrics that reflect the shape of the whole Deep Bootstrap posterior (the area under the receiver operating characteristic curve and the precision-recall curve). The metrics are calculated for different choice of n, p ’s, and on a separate testing set of size 100. The results are summarized in Table 1 which shows that samples generated from the Deep Bootstrap sampler are of high quality for various prediction-related metrics and are close to the target. In terms of predictive performance, the actual bootstrap and DBS are comparable. However, the computing times are dramatically different. We observe that the timing benefit of DBS increases as n or p grow larger.

In summary, this example shows that DBS approximates the true bootstrap posterior well in terms of predictive performance. However, the deep sampler is dramatically faster, especially in large (n, p) settings. The variance mismatch issue mentioned in Shin et al. (2020) exists, but is not fatal.

5.2 Bayesian LAD Regression

Least squares regression estimators tend to be less robust to outliers or heavy-tailed errors. When robustness becomes a concern, M-estimators (Huber and Ronchetti (2009)) are often used instead of least-square estimators. Given data $\{(y_i, \mathbf{x}_i) \in \mathbb{R} \otimes \mathbb{R}^p\}_{i=1}^n$ where \mathbf{x}_i denotes

the covariates of an observation with response y_i , a regression M-estimator is the minimizer of the loss

$$l(\beta, \boldsymbol{\theta}; y_i, \mathbf{x}_i) = g(y_i - \beta - \mathbf{x}_i^\top \boldsymbol{\theta}). \quad (5.5)$$

where $\beta \in \mathbb{R}$ is the intercept, $\boldsymbol{\theta} = (\theta_1, \dots, \theta_p) \in \mathbb{R}^p$ is the regression coefficient vector, and $g : \mathbb{R} \rightarrow [0, \infty)$ is a residual function that satisfies (i) $g(0) = 0$, (ii) $g(t) = g(-t)$, $\forall t \in \mathbb{R}$, (iii) g is monotonically increasing (Rousseeuw and Leroy (2005)). Statistical literature on robustness has proposed a variety of residual functions g , including the Huber function (Huber (1964))

$$g(t; \delta) = \begin{cases} \frac{1}{2}t^2, & \text{for } |t| \leq \delta \\ \delta \left(|t| - \frac{1}{2}\delta \right), & \text{otherwise} \end{cases}$$

and the absolute value function (Boscovich (1757)) $g(t) = |t|$. Here, we consider the case where g is the absolute value function, i.e., least absolute deviation (LAD) regression (Boscovich (1757)). A penalized LAD regression model is investigated in Lambert-Lacroix and Zwald (2011); Wang et al. (2007); Wang (2013); Wang et al. (2006); Zou (2006), which minimizes

$$\sum_{i=1}^n |y_i - \beta - \boldsymbol{\theta}^\top \mathbf{x}_i| + \lambda \sum_{j=1}^p |\theta_j|. \quad (5.6)$$

Note that the intercept β is excluded from the penalty term as suggested by Wang et al. (2006). In (5.6), the regularization strength λ can be selected from the classical BIC criteria as recommended by Lambert-Lacroix and Zwald (2011); Schwarz (1978).

Viewing (5.6) from a Bayesian viewpoint, minimizing (5.6) is equivalent to estimating the mode of a Bayesian model with a loss

$$l(\beta, \boldsymbol{\theta}; y_i) = |y_i - \beta - \boldsymbol{\theta}^\top \mathbf{x}_i|, \quad (5.7)$$

and a prior

$$\pi(\boldsymbol{\theta}) = \prod_{j=1}^p \left[\frac{\lambda}{2} e^{-\lambda|\theta_j|} \right]. \quad (5.8)$$

However, one might be interested in not only the posterior mode but also uncertainty quantification. The Gibbs posterior defined by (2.5) in Section 2.2 provides one such uncertainty measurement. We compute the Gibbs posterior using MCMC. Another possibility is to obtain approximations, either by directly solving the optimization problem defined in (3.1), or by using the deep Bootstrap sampler (Algorithm 2). This examples investigates these three objects for uncertainty quantification.

We simulate data following the settings in Lambert-Lacroix and Zwald (2011): n i.i.d. data points $\{(y_i, \mathbf{x}_i)\}_{i=1}^n$ are generated from

$$y_i = \beta^* + \mathbf{x}_i^\top \boldsymbol{\theta}^* + \sigma \epsilon_i, \quad \mathbf{x}_i \stackrel{\text{iid}}{\sim} N(0, \Sigma), \quad (5.9)$$

where $\beta^* = 1$, $\boldsymbol{\theta}^* = (1.5, 2, 3, 0, 0, \dots, 0) \in \mathbb{R}^p$, Σ is a Toeplitz matrix with $\Sigma_{i,j} = (0.5)^{|i-j|}$. Following Lambert-Lacroix and Zwald (2011)), we consider two challenging cases with heavy-tailed noise distribution:

Figure 3: Two-dimensional posterior density plot for θ_i 's in Model 1 for Bayesian LAD example. We set $n = 100, p = 8$. The location of true parameters are marked in red star. The location of the minimizer of Equation (5.6) are marked in black triangle.

- Model 1: large outliers. $\epsilon_i = v_i/\sqrt{\text{var}(v_i)}$, $\sigma = 9.67$, and $v_i \stackrel{\text{iid}}{\sim} 0.9N(0, 1) + 0.1N(225)$.
- Model 2: sensible outliers. $\epsilon_i = v_i/\sqrt{\text{var}(v_i)}$, $\sigma = 9.67$, and $v_i \stackrel{\text{iid}}{\sim} \text{Laplace}(1)$.

One may show that the solution to (2.4) equals the truth (i.e., $\theta_0 = (\beta, \boldsymbol{\theta}) = (\beta^*, \boldsymbol{\theta}^*)$) under some mild conditions as in Gross and Steiger (1979); Pollard (1991); Ruzinsky and Olsen (1989). We note that this equality holds for both Model 1 and 2. We investigate different choices of $n \in \{8, 10, 20, 50\}$ and $p \in \{100, 200, 500, 1000\}$.

Both the Gibbs posterior (2.5) and bootstrap samples (3.1) use the loss (5.7) and the prior (5.8), where the regularization strength λ in prior (5.8) is set to the one that minimizes the BIC criteria (Schwarz (1978)) among $\log(\lambda) \in \{-6, \dots, 1\}$ (an equi-spaced sequence starting at -6, ending at 1 and of length 20), as suggested by Lambert-Lacroix and Zwald (2011). For the Gibbs posterior, we set the learning rate $\alpha = 1$ to match (5.6) which is used to generate bootstrap samples. We refer readers to Bissiri et al. (2016) and Lyddon et al. (2019) for more discussion on the problem of determining α .

In practice, the Gibbs posterior is generated using the Metropolis-Hasting algorithm described in Chernozhukov and Hong (2003). We implement it in Python. For faster convergence, the starting value for $\theta_0, \boldsymbol{\theta}$ are set to the mode of the Gibbs posterior solved by QuantileRegressor. The proposal density $q(x | y)$ is set to the density of $N(y, \sigma' I_p)$. We set $\sigma' = 0.1$ for small data sets and $\sigma' = 0.01$ for large ones as the true Gibbs posterior tends to have smaller variance as the dimension grows. We run MCMC for 1 000 000 iterations and discard the first 10 000 as burn-in. Gelman-Rubin diagnostic (Gelman and Rubin (1992)) computed by R package coda (Plummer et al. (2006)) is checked to ensure convergence.

For the Bootstrap samples, we solve the optimization problem (3.1) with $w \sim n \times \text{Dir}(1, 1, \dots, 1)$, loss (5.7), and prior (5.8) using the built-in function QuantileRegressor. This function solves (3.1) by linear programming, and we use its default interior-point solver with default parameters. For the Deep Bootstrap sampler, we implement Algorithm 2 using Pytorch, with a subgroup size $S = 100$. The other settings, including network architecture, training schedule and hyper-parameters, are identical to the Bayesian support vector machine example.

Table 2: Evaluation of approximation properties in different settings based on 10 independent runs of Bayesian LAD regression. DBS standards for ‘Deep Bootstrap Sampler’. WLB standards for samples from the true bootstrap distribution. Coverage stands for the empirical coverage of 90% credible intervals. ‘Bias’ refers to the l_1 distance between estimated posterior means and the truth. We denote with + an average over active coordinates, and with - an average over inactive coordinates. Times reported are the number of seconds (unless otherwise noted) taken to generate 10 000 effective samples for each procedure. For deep Bootstrap sampler, time reported is in the form of training time + sampling time.

Let us first consider the posterior density of θ_j ’s. Figure 3 shows the two-dimensional posterior density plot in Model 1. Results for Model 2 are very similar and are included in the Appendix B.4. We observe that samples from all three methods are centered around the same location. The center is close to the minimizer of Equation (5.6), which is different from the truth due to shrinkage effects introduced from the prior. The Gibbs posterior tends to have the smallest variance, in contrast to the true Bootstrap samples which has the largest variance.

To quantitatively compare each method, we report the bias, lengths of 90% credible intervals and their coverage for various choice of (n, p) ’s in Table 2. We separate between active and inactive coordinates. Table 2 also includes the time cost for each method. For fairness, we compare the time required to generate the same number of effective samples. Since each sample from bootstrap is independent, we treat the total number of samples as the effective sample size for both bootstrap samplers. The effective sample size for Gibbs posterior is calculated using R package coda. Table 2 shows the deep Bootstrap sampler is much faster than both the true bootstrap and the Gibbs posterior, especially in large datasets.

We conclude that, in this example, DBS reconstructions could be a viable alternative to Gibbs posteriors. The Deep Bootstrap sampler achieves a similar bias and a larger variance, but is much faster than the Metropolis-Hastings algorithm.

6 Discussion

This paper surveys several recent contributions to the Bayesian literature on learning about parameters defined by loss functions. We highlighted a new promising direction for Bayesian computation using generative bootstrap. We demonstrated the potential of this new strategy on several examples. This paper aims to draw practitioners' attention towards posterior sampling techniques beyond the traditional MCMC technology.

A Proofs

A.1 Notations

First let us recall some notations. For a random variable X on a probability space (Ω, Σ, P) , we denote $\mathbb{P}(A) = \int_A dP$ for any $A \in \Sigma$, and $Ph = \int_{\Omega} hdP$ for any $h : \Omega \rightarrow \mathbb{R}$. We denote $[n] = \{1, 2, \dots, n\}$. We use $\|\cdot\|$ to denote Euclidean norm.

A.2 Proof of Lemma 4.1

Recall that

$$p_{\theta}^{(n), \mathbf{w}}(X^{(n)}) = \prod_{i=1}^n p_{\theta}^{w_i}(X_i) \quad \text{and} \quad p_{\theta_0}^{(n), 1-\mathbf{w}}(X^{(n)}) = \prod_{i=1}^n p_{\theta_0}^{1-w_i}(X_i).$$

By definition, we have

$$\begin{aligned} C_{\theta, \mathbf{w}} &= P_{\theta}^{(n)} \frac{p_{\theta_0}^{(n), 1-\mathbf{w}}(X^{(n)})}{p_{\theta}^{(n), 1-\mathbf{w}}(X^{(n)})} = \int_{\mathcal{X}} p_{\theta_0}^{(n), 1-\mathbf{w}}(X^{(n)}) p_{\theta}^{(n), \mathbf{w}}(X^{(n)}) dX^{(n)} \\ &= P_{\theta_0}^{(n)} \frac{p_{\theta}^{(n), \mathbf{w}}(X^{(n)})}{p_{\theta_0}^{(n), \mathbf{w}}(X^{(n)})} = P_{\theta_0}^{(n)} \left[\prod_{i=1}^n \frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right] \stackrel{(a)}{=} \prod_{i=1}^n \left[P_{\theta_0} \left(\frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right) \right], \end{aligned} \quad (\text{A.1})$$

where (a) follows from the independence of X_i 's. For any fixed \mathbf{w} , recall that $\theta_{\mathbf{w}}^*$ defined in (4.2) is the minimizer of the function $f_{\mathbf{w}}(\cdot)$, where

$$f_{\mathbf{w}}(\theta) = -P_{\theta_0}^{(n)} \log \frac{\tilde{p}_{\theta}^{(n), \mathbf{w}}(X^{(n)})}{p_{\theta_0}^{(n)}(X^{(n)})}.$$

Notice that

$$\begin{aligned} f_{\mathbf{w}}(\theta) &= -P_{\theta_0}^{(n)} \log \frac{\tilde{p}_{\theta}^{(n), \mathbf{w}}(X^{(n)})}{p_{\theta_0}^{(n)}(X^{(n)})} = -P_{\theta_0}^{(n)} \left[\sum_{i=1}^n -\log \frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} - \log C_{\theta, \mathbf{w}} \right] \\ &\stackrel{(a)}{=} \sum_{i=1}^n \left[P_{\theta_0} \left(\log \frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right) + \log P_{\theta_0} \left(\frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right) \right] \\ &\stackrel{(b)}{\geq} \sum_{i=1}^n \left[P_{\theta_0} \left(\log \frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right) + P_{\theta_0} \left(\log \frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} \right) \right] = 0, \end{aligned}$$

where (a) uses Equation (A.1), and (b) follows from Jensen's inequality. From properties of Jensen's inequality, (b) achieves equality if and only if $\frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)}$ is degenerate for every $i \in [n]$, i.e., there exist constants c_{w_i} for $i = 1, 2, \dots, n$ such that

$$\mathbb{P}_{\theta_0} \left(\frac{p_{\theta}^{w_i}(X_i)}{p_{\theta_0}^{w_i}(X_i)} = c_{w_i} \right) = 1, \quad \forall i = 1, 2, \dots, n.$$

From assumption (1), there must exist $k \in [n]$ such that $w_k > 0$ and thus, $\mathbb{P}_{\theta_0} \left(\frac{p_{\theta}(X_k)}{p_{\theta_0}(X_k)} = c_{w_k}^{1/w_k} \right) = 1$, i.e. $\frac{p_{\theta}(X_k)}{p_{\theta_0}(X_k)}$ is degenerate. From assumption (2), we then conclude that when (b) achieves equality, we must have $\theta = \theta_0$. Notice that setting $\theta = \theta_0$ indeed achieves equality in (b). Thus, $f_{\mathbf{w}}(\theta)$ is minimized iff $\theta = \theta_0$. This means that θ_0 is the unique minimizer of $f_{\mathbf{w}}(\theta)$.

A.3 Proof of Theorem 4.2

First, we introduce some notation and Assumptions. For any \mathbf{w} , let us define the usual ϵ -KL neighborhood around $\tilde{P}_{\theta_0}^{(n),\mathbf{w}}$ as

$$B(\epsilon, \mathbf{w}, \tilde{P}_{\theta_0}^{(n),\mathbf{w}}, P_{\theta_0}^{(n)}) = \left\{ \tilde{P}_{\theta}^{(n),\mathbf{w}} \in \tilde{\mathcal{P}}^{(n),\mathbf{w}} : K(\mathbf{w}, \theta_0) \leq n\epsilon^2, V(\mathbf{w}, \theta_0) \leq n\epsilon^2 \right\}$$

where

$$K(\mathbf{w}, \theta_0) = P_{\theta_0}^{(n)} \log \frac{\tilde{P}_{\theta_0}^{(n),\mathbf{w}}}{\tilde{P}_{\theta}^{(n),\mathbf{w}}}, \quad \text{and} \quad V(\mathbf{w}, \theta_0) = P_{\theta_0}^{(n)} \left| \log \frac{\tilde{P}_{\theta_0}^{(n),\mathbf{w}}}{\tilde{P}_{\theta}^{(n),\mathbf{w}}} - K(\mathbf{w}, \theta_0) \right|^2.$$

We denote with $Q_{\theta}^{(n)}$ a probability measure defined through $dQ_{\theta}^{(n),\mathbf{w}} = \frac{p_{\theta_0}^{(n)}}{\tilde{p}_{\theta_0}^{(n),\mathbf{w}}} dP_{\theta}^{(n)}$.

Assumption 1 (Existence of suitable semi-metric). *There exists a semi-metric $d(\cdot, \cdot)$ and some constant $C > 0$ such that for any sufficiently large $n \in \mathbb{N}$ and any $\mathbf{w} \in R_n(c_0)$,*

$$d(\tilde{P}_{\theta}^{(n),\mathbf{w}}, \tilde{P}_{\theta_0}^{(n),\mathbf{w}}) \geq C \|\theta - \theta_0\|, \quad \theta \in \Theta.$$

Assumption 2 (Existence of suitable tests). *For any $\epsilon > \epsilon_n$, there exists a test ϕ_n (depending on ϵ) such that for any $J \in \mathbb{N}_0$,*

$$P_{\theta_0}^{(n)} \phi_n \lesssim e^{-n\epsilon^2/4} \quad \text{and} \quad \sup_{\mathbf{w} \in R_n(c_0)} \sup_{\tilde{P}_{\theta}^{(n),\mathbf{w}} : d(\tilde{P}_{\theta}^{(n),\mathbf{w}}, \tilde{P}_{\theta_0}^{(n),\mathbf{w}}) > J\epsilon} Q_{\theta}^{(n),\mathbf{w}} (1 - \phi_n) \leq e^{-nJ^2\epsilon^2/4}.$$

Assumption 3 (Prior regularization). *There exists constant $L > 0$ such that for any sufficiently large $n, j \in \mathbb{N}$,*

$$\sup_{\mathbf{w} \in R_n(c_0)} \frac{\tilde{\Pi}_{\mathbf{w}}(\theta \in \Theta : j\epsilon_n < d(\tilde{P}_{\theta}^{(n),\mathbf{w}}, \tilde{P}_{\theta_0}^{(n),\mathbf{w}}) \leq (j+1)\epsilon_n)}{\tilde{\Pi}_{\mathbf{w}}(B(\epsilon, \mathbf{w}, \tilde{P}_{\theta_0}^{(n),\mathbf{w}}, P_{\theta_0}^{(n)}))} \leq Le^{\epsilon_n^2 j^2/8}.$$

Proof. Notice that

$$\begin{aligned} & P_{\theta_0}^{(n)} P_{\mathbf{w}} \left[\Pi_{\mathbf{w}}(\theta \in \Theta : \|\theta - \theta_0\| \geq M_n \epsilon_n \mid X^{(n)}) \right] \\ &= P_{\mathbf{w}} P_{\theta_0}^{(n)} \left[\Pi_{\mathbf{w}}(\theta \in \Theta : \|\theta - \theta_0\| \geq M_n \epsilon_n \mid X^{(n)}) \mathbb{I}(\mathbf{w} \in R_n) \right] \end{aligned} \tag{A.2}$$

$$\begin{aligned} & + P_{\mathbf{w}} P_{\theta_0}^{(n)} \left[\Pi_{\mathbf{w}}(\theta \in \Theta : \|\theta - \theta_0\| \geq M_n \epsilon_n \mid X^{(n)}) \mathbb{I}(\mathbf{w} \notin R_n) \right] \\ &= U_1 + U_2, \end{aligned} \tag{A.3}$$

where $U_1 = P_{\mathbf{w}} P_{\theta_0}^{(n)} \left[\Pi_{\mathbf{w}} \left(\theta \in \Theta : \|\theta - \theta_0\| \geq M_n \epsilon_n \mid X^{(n)} \right) \mathbb{I}(\mathbf{w} \in R_n) \right]$ and $U_2 = P_{\mathbf{w}} [\mathbb{I}(\mathbf{w} \notin R_n)]$. Now, we will bound U_1 and U_2 separately.

From Lemma 4.1, we have $\theta_{\mathbf{w}}^* = \theta_0$ for any \mathbf{w} . Thus, from Assumption 2, 3 and Theorem 11.1 in Kaji and Rockova (2021), we have for every sequence of constants $M_n \rightarrow \infty$, as $n \rightarrow \infty$,

$$P_{\theta_0}^{(n)} \left[\Pi_{\mathbf{w}} \left(\tilde{P}_{\theta}^{(n), \mathbf{w}} : d \left(\tilde{P}_{\theta}^{(n), \mathbf{w}}, \tilde{P}_{\theta_0}^{(n), \mathbf{w}} \right) \geq M_n \epsilon_n \mid X^{(n)} \right) \mathbb{I}(\mathbf{w}_n \in R_n(c_0)) \right] \rightarrow 0, \quad (\text{A.4})$$

where $\Pi_{\mathbf{w}}(\cdot \mid X^{(n)})$ is the probability measure with a density

$$\pi_{\mathbf{w}}(\theta \mid X^{(n)}) \propto \tilde{p}_{\theta}^{(n), \mathbf{w}}(X^{(n)}) \tilde{\pi}_{\mathbf{w}}(\theta).$$

From (A.4) and Assumption 1, we have

$$P_{\theta_0}^{(n)} \left[\Pi_{\mathbf{w}} \left(\theta \in \Theta : \|\theta - \theta_0\| \geq M_n \epsilon_n \mid X^{(n)} \right) \mathbb{I}(\mathbf{w}_n \in R_n(c_0)) \right] \rightarrow 0. \quad (\text{A.5})$$

Recall that Lemma 4.1 says $\theta_0 = \theta_{\mathbf{w}}^*$. Thereby, in Equation (A.5), the usual center $\theta_{\mathbf{w}}^*$ to which the posterior $\Pi_{\mathbf{w}}(\cdot \mid X^{(n)})$ concentrates is replaced by θ_0 (which does not depend on \mathbf{w}). The second term U_2 in (A.3) can be trivially bounded using Equation (4.3):

$$P_{\mathbf{w}} [\mathbb{I}(\mathbf{w} \notin R_n)] = \mathbb{P}_{\mathbf{w}}(\mathbf{w} \notin R_n) \rightarrow 0. \quad (\text{A.6})$$

Plugging (A.5) and (A.6) into (A.3), we get the desired conclusion. \square

A.4 Proof of Theorem 4.3

Proof. We will prove the case where $\mathbf{w}_n = (w_1, \dots, w_n)' \sim n \times \text{Dir}(c, \dots, c)$. The other case is similar and easier. First, note that if we choose $z_i \stackrel{\text{iid}}{\sim} \text{Gamma}(c, 1)$, we have

$$\left(\frac{z_1}{\sum_{i=1}^n z_i}, \dots, \frac{z_n}{\sum_{i=1}^n z_i} \right) \sim \text{Dir}(c, \dots, c).$$

This implies

$$\hat{\theta}_{\mathbf{w}} = \arg \min_{\theta} \left\{ \sum_{i=1}^n w_i \log p_{\theta}(X_i) + \log \pi(\theta) \right\}$$

and

$$\hat{\theta}_{\mathbf{z}} = \arg \min_{\theta} \left\{ \sum_{i=1}^n z_i \log p_{\theta}(X_i) + \frac{1}{n} \sum_{i=1}^n z_i \log \pi(\theta) \right\}, \quad \text{where } \mathbf{z} = (z_1, \dots, z_n) \quad (\text{A.7})$$

follows the same distribution. Thus, we focus on showing for any sequence $M_n \rightarrow \infty$,

$$P_0^{(n)} \left[\mathbb{P}_{\mathbf{z}} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > M_n \epsilon_n \mid X^{(n)} \right) \right] \rightarrow 0.$$

This is equivalent to showing for any sequence $M_n \rightarrow \infty$,

$$P_0^{(n)} \left[\mathbb{P}_{\mathbf{z}} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n \mid X^{(n)} \right) \right] \rightarrow 0.$$

Note that $\hat{\theta}_{\mathbf{z}}$ is a random variable where randomness comes from both \mathbf{z} and $X^{(n)}$. Since \mathbf{z} and $X^{(n)}$ are independent, denote the joint distribution of $X^{(n)}$ and \mathbf{z} as $P_{0,\mathbf{z}}^{(n)}$, i.e.,

$$(X^{(n)}, \mathbf{z}) \sim P_{0,\mathbf{z}}^{(n)}, \quad \text{where } dP_{0,\mathbf{z}}^{(n)} = dP_0^{(n)} \times dP_{\mathbf{z}}.$$

And write

$$\mathbb{P}_{0,\mathbf{z}}^{(n)}(A) = \int_A dP_{0,\mathbf{z}}^{(n)}.$$

Notice that from tower law, we have

$$\mathbb{P}_{0,\mathbf{z}}^{(n)} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n \right) = P_0^{(n)} \left[\mathbb{P}_{\mathbf{z}} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n \mid X^{(n)} \right) \right].$$

Define the shells

$$S_j = \left\{ \theta \in \Theta : 2^{j-1} \epsilon_n < d(\theta, \theta_0) \leq 2^j \epsilon_n \right\}, \quad \text{for } j = 1, 2, \dots$$

Then we have,

$$\begin{aligned} & \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n \right) \\ &= \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n, \sum_{i=1}^n z_i < 2cn \right) + \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(d(\hat{\theta}_{\mathbf{z}}, \theta_0) > 2^{M_n} \epsilon_n, \sum_{i=1}^n z_i \geq 2cn \right) \\ &\leq \sum_{j>M_n} \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(2^{j-1} \epsilon_n < d(\hat{\theta}_{\mathbf{z}}, \theta_0) \leq 2^j \epsilon_n, \sum z_i < 2cn \right) + \mathbb{P}_{\mathbf{z}} \left(\sum_{i=1}^n z_i \geq 2cn \right) \\ &= \sum_{j>M_n} \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\hat{\theta}_{\mathbf{z}} \in S_j, \sum_{i=1}^n z_i < 2cn \right) + \mathbb{P}_{\mathbf{z}} \left(\sum_{i=1}^n z_i \geq 2cn \right). \end{aligned}$$

Notice that by the weak law of large numbers, $\bar{z}_n = n^{-1} \sum_{i=1}^n z_i \xrightarrow{P} \mathbb{E} z_1 = c$, and thus,

$$\mathbb{P}_{\mathbf{z}} \left(\sum_{i=1}^n z_i \geq 2cn \right) = \mathbb{P}_{\mathbf{z}} (\bar{z}_n \geq 2c) \leq \mathbb{P}_{\mathbf{z}} (|\bar{z}_n - c| \geq c) \rightarrow 0.$$

Now, we will bound $\mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\hat{\theta}_{\mathbf{z}} \in S_j, \sum z_i < 2cn \right)$ for each $j > M_n$. Denote

$$\mathbb{M}_n(\theta) = \frac{1}{n} \sum_{i=1}^n z_i \log p_{\theta}(X_i), \quad \mathbb{M}(\theta) = P_0 \log p_{\theta}(X_i).$$

Recall the definition of $\hat{\theta}_{\mathbf{z}}$ in Equation (A.7). Thus, $\hat{\theta}_{\mathbf{z}} \in S_j$ implies

$$\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) + \frac{1}{n^2} \sum_{i=1}^n z_i \log \pi(\theta) \right) \geq \mathbb{M}_n(\theta_0) + \frac{1}{n^2} \sum_{i=1}^n z_i \log \pi(\theta_0).$$

Thus,

$$\begin{aligned}
& \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\hat{\theta}_{\mathbf{z}} \in S_j, \sum_{i=1}^n z_i < 2cn \right) \\
& \leq \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}_n(\theta_0) + \frac{1}{n^2} \sum_{i=1}^n z_i \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \geq 0, \sum_{i=1}^n z_i < 2cn \right) \\
& \leq \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}_n(\theta_0) + \frac{2c}{n} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \geq 0 \right).
\end{aligned}$$

We have

$$\begin{aligned}
& \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}_n(\theta_0) + \frac{2c}{n} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \geq 0 \right) \\
& \leq \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}(\theta) - \mathbb{M}_n(\theta_0) + \mathbb{M}(\theta_0) + \frac{2c}{n} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) + \sup_{\theta \in S_j} (-\mathbb{M}(\theta_0) + \mathbb{M}(\theta)) \geq 0 \right) \\
& = \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}(\theta) - \mathbb{M}_n(\theta_0) + \mathbb{M}(\theta_0) + \frac{2c}{n} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \geq \inf_{\theta \in S_j} P_0 \log [p_{\theta_0}/p_{\theta}] \right) \\
& \stackrel{(a)}{\leq} \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} ([\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]) + \frac{2c}{n} \sup_{\theta \in S_j} \log \frac{\pi(\theta)}{\pi(\theta_0)} \geq \inf_{\theta \in S_j} d^2(\theta_0, \theta) \right) \\
& \stackrel{(b)}{\leq} \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} ([\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]) \geq 2^{2j-2} \epsilon_n^2 - \frac{2c}{n} \sup_{\theta \in S_j} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \\
& \stackrel{(c)}{\leq} \mathbb{P}_{0,\mathbf{z}}^{(n)} \left(\sup_{\theta \in S_j} ([\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]) \geq 2^{2j-3} \epsilon_n^2 \right) \\
& \stackrel{(d)}{\leq} \frac{P_{0,\mathbf{z}}^{(n)} \left[\sup_{\theta \in S_j} |[\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]| \right]}{2^{2j-3} \epsilon_n^2}, \tag{A.8}
\end{aligned}$$

where (a) follows from Assumption (1), (b) follows the definition of S_j , (c) follows from the second part of (4.6), which says when n is sufficiently large, the following holds uniformly for all $j \geq 1$,

$$2^{2j-2} \epsilon_n^2 - \frac{2c}{n} \sup_{\theta \in S_j} \log \frac{\pi(\theta)}{\pi(\theta_0)} > 2^{2j-2} \epsilon_n^2 - \frac{1}{2} 2^{2j-2} \epsilon_n^2 = 2^{2j-3} \epsilon_n^2,$$

and (d) follows from Markov's inequality. Now, our task is to bound the numerator in (A.8). Notice that

$$\begin{aligned}
& P_{0,\mathbf{z}}^{(n)} \left[\sup_{\theta \in S_j} |[\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]| \right] \\
& = P_{0,\mathbf{z}}^{(n)} \left[\sup_{\theta \in S_j} \left| \frac{1}{n} \sum_{i=1}^n z_i \log \frac{p_{\theta}(X_i)}{p_{\theta_0}(X_i)} - P_0 \log \frac{p_{\theta}(X_i)}{p_{\theta_0}(X_i)} \right| \right]
\end{aligned}$$

$$\begin{aligned}
&= P_{0,z}^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{n} \sum_{i=1}^n (z_i - 1) \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} + \frac{1}{n} \sum_{i=1}^n \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} - P_0 \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right] \\
&\leq P_{0,z}^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{n} \sum_{i=1}^n (z_i - 1) \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right] + P_0^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{n} \sum_{i=1}^n \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} - P_0 \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right].
\end{aligned}$$

We will bound the two terms in the last line separately.

First, from Lemma 2.9.1 in [Van der Vaart and Wellner \(1996\)](#) and Assumption (2), we have

$$\begin{aligned}
&P_{0,z}^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{n} \sum_{i=1}^n (z_i - 1) \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right] \\
&\leq 2\sqrt{2n^{-1}} \|z_1 - 1\|_{2,1} \max_{k \in [n]} P_{0,z}^{(k)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{\sqrt{k}} \sum_{i=1}^k \sigma_i \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right] \\
&\leq C_1 n^{-1/2} \max_{k \in [n]} \sqrt{k} \mathcal{R}_k(\mathcal{M}_{2^j \epsilon_n}(\theta_0)).
\end{aligned}$$

By symmetrization inequality (Lemma 2.3.1 in [Van der Vaart and Wellner \(1996\)](#)),

$$P_0^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} \left| \frac{1}{n} \sum_{i=1}^n \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} - P_0 \log \frac{p_\theta(X_i)}{p_{\theta_0}(X_i)} \right| \right] \leq 2\mathcal{R}_n(\mathcal{M}_{2^j \epsilon_n}(\theta_0)).$$

Thus, we have

$$\begin{aligned}
&P_{0,z}^{(n)} \left[\sup_{\theta \in \mathcal{S}_j} |[\mathbb{M}_n(\theta) - \mathbb{M}(\theta)] - [\mathbb{M}_n(\theta_0) - \mathbb{M}(\theta_0)]| \right] \\
&\leq C_1 \frac{\max_{k \in [n]} \sqrt{k} \mathcal{R}_k(\mathcal{M}_{2^j \epsilon_n}(\theta_0))}{\sqrt{n}} + 2\mathcal{R}_n(\mathcal{M}_{2^j \epsilon_n}(\theta_0)) \\
&\leq C_2 n^{-1/2} \max_{k \in [n]} \phi_k(2^j \epsilon_n).
\end{aligned}$$

Plugging into [\(A.8\)](#), we get

$$\mathbb{P}_{0,z}^{(n)} \left(\sup_{\theta \in \mathcal{S}_j} \left(\mathbb{M}_n(\theta) - \mathbb{M}_n(\theta_0) + \frac{2c}{n} \log \frac{\pi(\theta)}{\pi(\theta_0)} \right) \geq 0 \right) \leq \frac{C_2 n^{-1/2} \max_{k \in [n]} \phi_k(2^j \epsilon_n)}{2^{2j-3} \epsilon_n^2}.$$

By assumption, $\phi_k(2^j \epsilon_n) \leq 2^{\gamma j} \phi_k(\epsilon_n)$ and thus

$$\mathbb{P}_{0,z}^{(n)} \left(d(\hat{\theta}_z, \theta_0) > 2^M \epsilon_n \right) \leq C_4 \frac{\max_{k \in [n]} \phi_k(\epsilon_n)}{8\sqrt{n} \epsilon_n^2} \sum_{j > M_n} 2^{(\gamma-2)j}.$$

As $M_n \rightarrow \infty$, we have $\sum_{j > M_n} 2^{(\gamma-2)j} \rightarrow 0$. And from assumption (4), we have

$$\frac{\max_{k \in [n]} \phi_k(\epsilon_n)}{\sqrt{n} \epsilon_n^2} \leq C_5,$$

thus,

$$C_4 \frac{\max_{k \in [n]} \phi_k(\epsilon_n)}{8\sqrt{n} \epsilon_n^2} \sum_{j > M_n} 2^{(\gamma-2)j} \rightarrow 0,$$

which implies $\mathbb{P}_{0,z}^{(n)} \left(d(\hat{\theta}_z, \theta_0) > 2^M \epsilon_n \right) \rightarrow 0$. \square

B Additional Experimental Results

This section presents additional experimental results mentioned in the main text. We include investigations into (a) the influence of network complexity, (b) the influence of regularization strength, and (c) additional results on Bayesian SVM and Bayesian LAD.

B.1 Influence of Network Complexity

We investigate the influence of complexity of the deep neural network on the approximating performance of the Deep Bootstrap sampler. We consider both the influence from the depth and the width of the architecture. Results are summarized in Table 3 where Table 3a investigates the depth while Table 3b investigates the width. We observe that in both tables, the Deep Bootstrap sampler is not very sensitive to the complexity. As the depth (or width) further increases, the marginal gain from increasing the complexity becomes less and less important.

Setting	metric width	$n = 100, p = 8$						$n = 1000, p = 50$					
		coverage		length of 90% CI		bias		coverage		length of 90% CI		bias

(b) Fixing depth (2 for $n = 100, p = 8$ and 3 for $n = 1000, p = 50$).

Table 3: Sensitivity analysis for deep Bootstrap sampler in Bayesian LAD regression example. We consider Model 2 with different (n, p) 's. ‘DBS’ stands for deep Bootstrap sampler. ‘WLB’ standards for samples from the true bootstrap distribution. Coverage stands for the empirical coverage of 90% confidence intervals. ‘Bias’ refers to the l_1 distance between estimated posterior means and the truth. We denote with + an average over active coordinates, and with - an average over inactive coordinates. Results are averaged over 10 independently generated data sets.

B.2 Influence of Regularization Strength

In examples in the main text, we choose the regularization parameter (α for Bayesian NPL and λ for Gibbs posterior) either subjectively or by consulting classic model selection criteria. One intriguing question is whether the regularization strength has an impact on

approximating performance of the deep Bootstrap sampler, and if there is, how. This subsection investigates this question.

Influence of λ in Gibbs posterior. Let us consider the classic LASSO regression example. Given data $\{(y_i, \mathbf{x}_i) \in \mathbb{R} \otimes \mathbb{R}^p\}_{i=1}^n$ where \mathbf{x}_i denotes the covariates of an observation with response y_i and assume a linear model, LASSO regression solves the penalized regression problem

$$\sum_{i=1}^n l(\boldsymbol{\theta}; y_i, \mathbf{x}_i) + \lambda \sum_{j=1}^p |\theta_j|,$$

which is equivalent to a the MAP of a Gibbs posterior with loss

$$l(\boldsymbol{\theta}; y_i, \mathbf{x}_i) = (y_i - \boldsymbol{\theta}^\top \mathbf{x}_i),$$

and prior

$$\pi(\boldsymbol{\theta}) = \prod_{j=1}^p \left[\frac{\lambda}{2} e^{-\lambda |\theta_j|} \right].$$

Here we assume the covariates and response are both centered so intercept is not included. One can use BIC strategy similar to that in Section 5.2 to choose the regularization strength λ . Yet here we will investigate different choices of λ 's and its effect on the deep Bootstrap sampler.

We simulate data following the settings in Nie and Ročková (2022). We generate n i.i.d. pairs (\mathbf{x}_i, y_i) from

$$y_i = \mathbf{x}_i^\top \boldsymbol{\theta} + \epsilon_i, \quad \mathbf{x}_i \stackrel{\text{iid}}{\sim} N(\mathbf{0}_p, \Sigma), \quad \epsilon_i \stackrel{\text{iid}}{\sim} N(0, 1).$$

with $n = 1000, p = 50$, and ρ a $p \times p$ matrix with all 1's on the diagonal and ρ 's off-diagonally. We consider $\rho = 0.6$.

The Bootstrap truth is computed using the function `linear_model.Lasso` in Python library `sklearn` Pedregosa et al. (2011).

We plot the 95% confidence interval from both the Bootstrap target and the deep Bootstrap sampler for different value of λ 's, i.e., the so-called 'solution path'. The plot is shown in Figure 4. We observe that in both correlation structures, as regularization parameter λ grows, the degree of underestimation for deep Bootstrap sampler also grows.

Influence of α in Bayesian NPL. We consider also the Bayesian support vector machine example introduced in Section 5.1, with $\rho = 0.6$. Note that in Bayesian NPL, the effect of α is analogous to λ in Gibbs posterior. So we make a similar solution path for varying α 's in Figure 5. Again, we observe that as α increases, in general the degree of underestimation also increases, which is consistent to our observations in the previous example.

Figure 4: LASSO solution path for the 4 active coordinates from deep Bootstrap sampler (blue line) and Bootstrap truth (orange line). We set $n = 1000, p = 50, \rho = 0.6$. The active coordinates are $\theta_{active} = (1, 2, -2, 3)'$. Each subfigure corresponds to one active coordinate.

Figure 5: Solution path for the Bayesian support vector machine example. We set $n = 50, p = 10, \rho = 0.6$.

Conclusion. We conclude that regularization strength has an impact on the performance of deep Bootstrap samplers. In general, the larger the regularization strength is, the more severe the variance underestimation problem is.

B.3 Additional Results on Bayesian Support Vector Machine

We present results on the Bayesian support vector machine for the independent case ($\rho = 0$). The two-dimensional density plots are shown in Figure 6. We observe that the posterior mean is captured well, while variance is more underestimated compared to correlated case. It is because with independent covariates, this is a simple problem, where similar and small values of (β, θ) will always yield a small loss, regardless of the input weight \mathbf{w} . Consequently, variation in the input weight \mathbf{w} 's only turned into small variation over output $\hat{G}(\mathbf{w})$. We note that this issue does not affect the predictive performance, which is shown in Table 4.

Figure 6: Two-dimensional posterior density plot for θ_i 's from deep Bootstrap sampler and the truth for Bayesian support vector machine example. We set $n = 50, p = 10, \rho = 0, \alpha = 1.0$.

Setting	Equi-correlated $\rho = 0.6$							
	metric	accuracy	precision	recall	F1	ROC	PR	time
$p = 10, n = 50$	DBS	0.99	1.00	0.99	0.99	1.00	1.00	54.68+0.65
	WLB	1.00	1.00	1.00	1.00	1.00	1.00	176.20
$p = 50, n = 500$	DBS	1.00	1.00	1.00	1.00	1.00	1.00	100.92+0.65
	WLB	1.00	1.00	1.00	1.00	1.00	1.00	199.98
$p = 100, n = 1000$	DBS	1.00	1.00	1.00	1.00	1.00	1.00	256.87+0.87
	WLB	1.00	1.00	1.00	1.00	1.00	1.00	548.26
$p = 200, n = 2000$	DBS	1.00	1.00	1.00	1.00	1.00	1.00	378.68+0.80
	WLB	1.00	1.00	1.00	1.00	1.00	1.00	1130.23
$p = 500, n = 5000$	DBS	1.00	1.00	1.00	1.00	1.00	1.00	559.22+0.64
	WLB	1.00	1.00	1.00	1.00	1.00	1.00	6256.95

Table 4: Evaluation of approximation properties based on 10 independent runs for Bayesian support vector machine example. DBS standards for ‘deep Bootstrap sampler’. WLB standards for samples from the true bootstrap distribution. ‘Bias’ refers to the l_1 distance of estimated posterior means. ‘ROC’ refers to the area under the receiver operating characteristic curve; ‘PR’ refers to the area under the precision-recall curve. The last column in each setting represents the time (in seconds) to generate 10 000 sample points. For deep Bootstrap sampler, time reported is in the form of training time + sampling time.

To confirm our hypothesis on the reason of variance underestimation in this example, we conduct the same experiments but on a more challenging setting where

$$\mathbb{P}(y_i = 1) = \mathbb{P}(y_i = -1) = 1/2, \quad \mathbf{x}_i | y_i \sim N(0.3y_i \mathbf{1}_p, \Sigma), \quad (\text{B.1})$$

where Σ is a $p \times p$ matrix with all 1's on the diagonal and 0's off-diagonally. We note that the signal strength in this model is smaller than that in the original setting (5.3), and thus this problem is more difficult in terms of prediction. We set the same prior strength $\alpha = 1$ as the original example. The posterior density plot for θ_i 's from this model are shown in Figure 7. Comparing Figure 7 with Figure 6, we observe that in the easier setting, the variance underestimation issue is more severe, which confirms our previous hypothesis.

Figure 7: Two-dimensional posterior density plot for θ_i 's from deep Bootstrap sampler and the truth for Bayesian support vector machine example. We set $n = 50, p = 10, \rho = 0, \alpha = 1.0$, and the data are generated using a more challenging setting (B.1).

B.4 Additional Results on Bayesian LAD Regression

Here we present additional results for Bayesian LAD regression, Model 2. The two-dimensional density plot is shown in Figure 8. Again we observe the same location for all methods, yet smaller variance for Gibbs posterior as compared to Bootstrap samples. Posterior from deep Bootstrap sampler is very close to the Bootstrap truth.

Figure 8: Two-dimensional posterior density plot for θ_i 's from Model 2 for Bayesian LAD example. We set $n = 100, p = 8$. The location of true parameters are marked in red star. The location of the minimizer of Equation (5.6) are marked in black triangle.
